Abstract

Locally Optimal Block Preconditioned Conjugate Gradient (LOBPCG) is widely used to compute eigenvalues of large sparse symmetric matrices. The algorithm can suffer from numerical instability if it is not implemented with care. This is especially problematic when the number of eigenpairs to be computed is relatively large. We present a number of techniques to improve the robustness and efficiency of this algorithm. We show that our approach consistently and significantly outperforms previous competing approaches in both stability and speed. We also present a robust convergence criterion which is backward stable.

Keywords: Symmetric eigenvalue problem, LOBPCG, numerical stability

1 Introduction

Locally Optimal Block Preconditioned Conjugate Gradient (LOBPCG) [7] is a widely used algorithm for computing a few algebraically smallest (or largest) eigenvalues and the corresponding eigenvectors of a Hermitian-definite matrix pencil (A, B) in which A is Hermitian and B is Hermitian positive definite. When B is the identity, the problem becomes a standard symmetric eigenvalue problem.

There are three main advantages of this method when compared with the classical Krylov subspace based methods. First, LOBPCG can employ a good preconditioner when one is available. The use of a preconditioner can dramatically reduce the number of iterations and computation time. Second, the three-term recurrence used by the algorithm keeps memory requirement relatively low, thereby making it possible to tackle problems at a very large scale. Third, because the algorithm is blocked, it can be implemented efficiently on modern parallel computers. Nearly every component of the algorithm can be formulated in level-3 dense or sparse BLAS operations [5, 10] that are highly tuned in several mathematical software libraries (e.g., ACML, Cray LibSci, Intel MKL, etc.) for efficient parallel scaling.

However, it has been observed that the algorithm can breakdown or suffer from numerical instability when it is not implemented carefully. In particular, basis vectors forming the subspace from which the approximate solution to the eigenvalue problem is extracted can become linearly

dependent. This problem becomes progressively worse when the number of eigenpairs to be computed becomes relatively large (e.g., hundreds or thousands). For example, in electronic structure calculations, the number of desired eigenpairs is proportional to the number of atoms in the system, which can grow to several thousands [11]. Hence remedies for improving numerical stability are of practical interest.

A strategy proposed in the work of Hetmaniuk and Lehoucq [6] addresses this issue. Their strategy is based on performing additional orthogonalization to ensure that the preconditioned gradient is numerically B -orthogonal to both the current and the previous approximations to the desired eigenvectors. However, this strategy can become expensive when the number of eigenpairs to be computed is relatively large. More importantly, reliability can still be severely compromised due to numerical instability within the orthogonalization steps.

This paper presents an efficient and reliable implementation of LOBPCG. We develop a number of techniques to significantly enhance the Hetmaniuk–Lehoucq (HL) orthogonalization strategy in both efficiency and reliability. We also adopt an alternative convergence criterion to ensure achievable error control in computed eigenpairs. For simplicity, we assume that both A and B are real matrices. But our techniques naturally carry over to complex Hermitian matrices.

The rest of this paper is organized as follows. In Section 2, we describe the basic LOBPCG algorithm. In Section 3, we discuss numerical difficulties one may encounter in LOBPCG and the HL strategy for overcoming these difficulties. In Section 4, we present our techniques for improving the HL strategy. In Section 5, we present additional techniques for improving all other aspects of LOBPCG. Finally, in Section 6, we report numerical experimental results to illustrate the effectiveness of our techniques.

2 The basic LOBPCG algorithm

We denote the eigenvalues of the symmetric-definite pencil (A, B) arranged in an increasing order by $\lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_n$. Their corresponding eigenvectors are denoted by x_1, x_2, \dots, x_n . The first $k \leq n$ eigenvectors and eigenvalues are given by $X = [x_1, x_2, \dots, x_k]$ and $\Lambda = \text{diag}\{\lambda_1, \lambda_2, \dots, \lambda_k\}$, respectively, satisfying $AX = BX\Lambda$. It is well known that X is the solution to the trace minimization problem

$$\min_{X^T B X = I} \text{trace}(X^T A X). \quad (1)$$

The LOBPCG algorithm developed by Knyazev seeks to solve (1) by using the updating formula

$$X^{(i+1)} = X^{(i)} C_1^{(i+1)} + X_{\perp}^{(i)} C_2^{(i+1)},$$

for eigenvector approximation, where $X_{\perp}^{(i)} = [W^{(i)}, P^{(i)}]$. Parenthetical superscript indices indicate the matrix is stored in an array that will be overwritten by subsequent iterations. The block $W^{(i)}$ is the preconditioned gradient of the Lagrangian

$$\mathcal{L}(X, \Lambda) = \frac{1}{2} \text{trace}(X^T A X) - \frac{1}{2} \text{trace}[(X^T B X - I)\Lambda] \quad (2)$$

associated with (1) at $X^{(i)}$,

$$W^{(i)} = K^{-1}(AX^{(i)} - BX^{(i)}\Theta^{(i)})$$

with $\Theta^{(i)} = X^{(i)T} A X^{(i)}$, where K is any preconditioner. The block $P^{(i)}$ is an aggregated update direction from previous searches recursively defined as

$$P^{(i+1)} = X_{\perp}^{(i)} C_2^{(i+1)},$$

with $P^{(1)}$ being an empty block, i.e., $X_{\perp}^{(1)} = W^{(1)}$.

Coefficient matrices $C_1^{(i+1)}$ and $C_2^{(i+1)}$ are determined at each step of LOBPCG by solving the constrained minimization problem (1) within the subspace $\mathcal{S}^{(i)}$ spanned by $X^{(i)}$, $W^{(i)}$, and $P^{(i)}$. That is,

$$\left(S^{(i)T} A S^{(i)} \right) C^{(i+1)} = \left(S^{(i)T} B S^{(i)} \right) C^{(i+1)} \Theta^{(i+1)}, \quad (3)$$

where $S^{(i)}$ is a matrix whose columns are a basis of $\mathcal{S}^{(i)}$ which is constructed as $S^{(i)} = \begin{bmatrix} X^{(i)} & X_{\perp}^{(i)} \end{bmatrix}$ with corresponding

$$C^{(i+1)} = \begin{bmatrix} C_1^{(i+1)} & C_{1\perp}^{(i+1)} \\ C_2^{(i+1)} & C_{2\perp}^{(i+1)} \end{bmatrix}.$$

The leading k columns of $C^{(i+1)}$ form

$$C_x^{(i+1)} = \begin{bmatrix} C_1^{(i+1)} \\ C_2^{(i+1)} \end{bmatrix}$$

which are the components used to compute $X^{(i+1)}$. Remaining columns give the orthogonal complement within the search subspace.

The diagonal matrix $\Theta^{(i+1)}$ in (3) contains approximations to the desired eigenvalues. If k smallest eigenpairs are sought then eigenvalues are sorted in ascending order; otherwise if the largest eigenpairs are sought the order is reversed. Solving the projected eigenvalue problem (3) is often referred to as the *Rayleigh–Ritz procedure*. Combining these steps produces Algorithm 1, the basic LOBPCG algorithm. We leave details of convergence control to Section 4.

3 Numerical stability and basis selection

A potential numerical instability issue can occur in Algorithm 1 within the Rayleigh–Ritz procedure shown in Algorithm 2, which is used to solve (3). This is due to the fact that the projection $S^T B S$ can be ill-conditioned or rank deficient, which can happen regardless of the conditioning of B .

When S is not B -orthonormal, we need to first perform a Cholesky factorization of $S^T B S$ to obtain an upper triangular factor R that is used to transform the generalized eigenvalue problem into a standard eigenvalue problem

$$\left[R^{-T} (S^T A S) R^{-1} \right] Z = Z \Theta, \quad (4)$$

where $R^T R = S^T B S$. The eigenvectors of pencil $(S^T A S, S^T B S)$ can be recovered by $C = R^{-1} Z$.

When $S^T B S$ is poorly conditioned or numerically singular, Cholesky factorization may fail. Even if the factorization succeeds, R may be poorly conditioned. This poorly conditioned R introduces significant roundoff error in the transformed problem (4) as well as the final transformation $C = R^{-1} Z$. This is often problematic since the near linear dependency of columns in S naturally

Algorithm 1 The basic LOBPCG algorithm

Input:

- $X^{(0)}$ is $m \times n_x$ matrix of initial approximate eigenvectors.
- $n_v \leq n_x$ is the number of converged eigenvectors requested.
- τ is the threshold used to determine eigenpair convergence.

Output:

- X is $m \times n_v$ matrix of approximate eigenvectors.
- Λ is $n_v \times n_v$ diagonal matrix of approximate eigenvalues.

```
1: function  $[X, \Lambda] = \text{lobpcgK}(X^{(0)}, n_v, \tau)$ 
2:    $[C^{(1)}, \Theta^{(1)}] = \text{RayleighRitz}(X^{(0)})$ .
3:    $X^{(1)} = X^{(0)}C^{(1)}$ .
4:    $R^{(1)} = AX^{(1)} - BX^{(1)}\Theta^{(1)}$ .
5:    $P^{(1)} = []$ .
6:   do  $i = 1, 2, \dots$ 
7:      $W^{(i)} = K^{-1}R^{(i)}$ .
8:      $S^{(i)} = [X^{(i)}, W^{(i)}, P^{(i)}]$ .
9:      $[C^{(i+1)}, \Theta^{(i+1)}] = \text{RayleighRitz}(S^{(i)})$ .
10:     $X^{(i+1)} = S^{(i)}C^{(i+1)}(:, 1 : n_x)$ .
11:     $R^{(i+1)} = AX^{(i+1)} - BX^{(i+1)}\Theta^{(i+1)}$ .
12:     $P^{(i+1)} = S^{(i)}(:, n_x + 1 : \text{end})C^{(i+1)}(n_x + 1 : \text{end}, :)$ .
13:    Determine number of converged eigenpairs  $n_c$ .
14:  while  $n_c < n_v$ 
15:    Return converged eigenpairs in  $X$  and  $\Lambda$ .
16: end function
```

Algorithm 2 Rayleigh–Ritz procedure

Input:

- S is $m \times n_s$ matrix basis for the search subspace.
- *Columns must be linearly independent and well-conditioned with respect to the metric B .

Output:

```
 $C, \Theta \in \mathbb{R}^{n_s \times n_s}$  that satisfy  $C^T(S^TBS)C = I_{n_s}$  and  $C^T(S^TAS)C = \Theta$ , where  $\Theta$  is diagonal.
1: function  $[C, \Theta] = \text{RayleighRitz}(S)$ 
2:    $D = (\text{diag}(S^TBS))^{-1/2}$ .
3:   Cholesky factorize  $R^TR = DS^TBSD$ .
4:   Solve symmetric eigenvalue problem  $(R^{-T}DS^TASDR^{-1})Z = Z\Theta$ .
5:    $C = DR^{-1}Z$ .
6: end function
```

emerges when some columns of $X^{(i)}$ become accurate eigenvector approximations. The corresponding columns in both $W^{(i)}$ and $P^{(i)}$ become small in magnitude. They are often sources of potential loss of accuracy and stability. We refer to [4] for further analysis.

A proper implementation of the LOBPCG algorithm should deflate converged eigenvectors by keeping them in $X^{(i)}$ but exclude corresponding columns from $W^{(i)}$ and $P^{(i)}$. This technique is referred to as *soft locking* [8]. In order to produce reliable results, approximate eigenpairs (Ritz

pairs) should be locked in order, i.e., the $(j + 1)$ st Ritz pairs cannot be locked if the j th Ritz pairs does not satisfy the convergence criterion. Some implementations allow out-of-order locking which can lead to slightly better performance. But this approach risks missing desired eigenpairs before termination.

Another technique that helps overcome poor scaling is to normalize each column of $W^{(i)}$ and $P^{(i)}$ before performing the Rayleigh–Ritz procedure. This is equivalent to scaling $S^T BS$ by a diagonal matrix D . Note that R^{-1} (or R^{-T}) is applied three times in (4) and in $C = R^{-1}Z$. The diagonal scaling step often dramatically reduces the condition number of R and hence improves the numerical stability.

Unfortunately, neither soft locking nor simple diagonal scaling can completely eliminate the numerical instability that potentially leads to a breakdown. It is observed that even with soft locking and diagonal scaling, $S^T BS$ can still become ill-conditioned. When the number of eigenpairs to be computed is relatively large, $S^T BS$ can become ill-conditioned before any approximate eigenvectors in $X^{(i)}$ are sufficiently accurate. This type of failure is quite common and is observed in some of the test cases we present in Section 6. We also provide a concrete example of this phenomenon in Section 4.1.

Hetmaniuk and Lehoucq (HL) proposed in [6] a way to overcome the numerical difficulty associated with ill-conditioning in $S^T BS$. Their basic approach is to keep the X , W and P blocks in the subspace \mathcal{S} mutually B -orthogonal. They refer to this as a basis selection strategy for \mathcal{S} .

Assuming the blocks $X^{(i)}$ and $P^{(i)}$ are B -orthonormal already, the basis selection strategy proposed by HL is performed in two steps on each iteration:

1. Before the Rayleigh–Ritz procedure, $W^{(i)}$ is obtained from residuals and then B -orthogonalized against both $X^{(i)}$ and $P^{(i)}$. Columns of $W^{(i)}$ are then B -orthonormalized.
2. After the Rayleigh–Ritz procedure has been performed, $P^{(i+1)}$ is implicitly B -orthogonalized against $X^{(i+1)}$. This is done by forming $C_p^{(i+1)}$ from

$$\begin{bmatrix} 0 \\ C_2^{(i+1)} \end{bmatrix}$$

which is orthogonalized against $C_x^{(i+1)}$ in the metric defined by $S^{(i)T}BS^{(i)}$. The result is then orthonormalized in the same metric producing fully orthonormal blocks $X^{(i+1)} = S^{(i)}C_x^{(i+1)}$ and $P^{(i+1)} = S^{(i)}C_p^{(i+1)}$.

HL use a procedure `ortho()` to carry out both of these orthogonalization steps. For implementation, they refer to the SVQB algorithm developed by Stathopolous and Wu [12]. The procedure `ortho()` operates in two nested loops. In the outer loop a candidate basis is orthogonalized against an existing orthonormal basis, called the external basis, using block classical Gram–Schmidt process. In the inner loop, the remainder is orthonormalized using the singular value decomposition. This is done by a function called `svqb()`. These procedures are outlined in Algorithms 3 and 4, respectively. We altered the original versions of these algorithms slightly to incorporate a metric M which will be used as either $M = B$ or $M = S^T BS$. The original versions only considered the standard Euclidean metric, i.e., $M = I$.

By constructing an orthonormal basis for \mathcal{S} , HL are able to turn the generalized eigenvalue problem (3) into a standard eigenvalue problem in the Rayleigh–Ritz procedure. Thus Cholesky factorization of the projection $S^T BS$ becomes unnecessary.

Algorithm 3 Block orthogonalization algorithm proposed by Stathopolous and Wu.

Input:

- M is $m \times m$ symmetric positive definite metric.
- $U^{(\text{in})}$ is $m \times n_u$ candidate basis.
- V is M -orthonormal external basis.
- $\tau_{\text{ortho}} > 0$ is relative orthogonality tolerance.

Output:

- $U^{(\text{out})}$ is $m \times n_u$ with M -orthonormal columns that are M -orthogonal to V .
 - $\text{span}([U^{(\text{out})}, V]) \supseteq \text{span}([U^{(\text{in})}, V])$.
 - 1: **function** $U^{(\text{out})} = \text{ortho}(M, U^{(\text{in})}, V, \tau_{\text{ortho}})$
 - 2: Set τ_{replace} .
 - 3: **do** $i = 1, 2, \dots$
 - 4: $U = U - V(V^T M U)$.
 - 5: **do** $j = 1, 2, \dots$
 - 6: $U = \text{svqb}(M, U, \tau_{\text{replace}})$.
 - 7: **while** $\frac{\|U^T M U - I_{n_u}\|}{\|MU\| \|U\|} > \tau_{\text{ortho}}$
 - 8: **while** $\frac{\|V^T M U\|}{\|MV\| \|U\|} > \tau_{\text{ortho}}$
 - 9: **end function**
-

Algorithm 4 Orthonormalization algorithm using SVD proposed by Stathopolous and Wu.

Input:

- M is $m \times m$ symmetric positive definite metric.
- $U^{(\text{in})}$ is $m \times n_u$.
- $\tau_{\text{replace}} > 0$ is tolerance.

Output:

- $U^{(\text{out})}$ is $m \times n_u$ with M -orthonormal columns.
 - $\text{span}(U^{(\text{out})}) \supseteq \text{span}(U^{(\text{in})})$.
 - 1: **function** $U^{(\text{out})} = \text{svqb}(M, U^{(\text{in})}, \tau_{\text{replace}})$
 - 2: $D = (\text{diag}(U^T M U))^{-1/2}$.
 - 3: Solve $(DU^T M U D) Z = Z \Theta$ for Z, Θ .
 - 4: **for all** $\theta_j < \tau_{\text{replace}} \max_i (|\theta_i|)$ **do**
 - 5: $\theta_j = \tau_{\text{replace}} \max_i (|\theta_i|)$.
 - 6: **end for**
 - 7: $U = U D Z \Theta^{-1/2}$.
 - 8: **end function**

4 Stability improvements

4.1 Basis truncation

Although the HL basis selection algorithm is plausible and has been demonstrated to work well for a practical problem in [6], its effectiveness hinges on the success of `ortho()` in producing an orthonormal basis $S^{(i)}$.

When source columns in $S^{(i)}$ are nearly linearly dependent, the orthogonalization procedure

proposed by Stathapoulos and Wu might not improve the basis; see [4]. Depending on the implementation, `ortho()` may fail to terminate because the orthogonality error threshold might never be satisfied. This is possible even when B is the identity and becomes more vexing when B is ill-conditioned.

Even if `ortho()` terminates after potentially numerous iterations, the returned basis might be so poorly conditioned that some eigenvalues of $S^T A S$ are spurious. That is, they do not represent an approximation to any eigenvalue of A .

The following example illustrates how this problem could occur. Let

$$A = \begin{bmatrix} 3 & 1 & & & & \\ 1 & 3 & 1 & & & \\ & 1 & 3 & 1 & & \\ & & \ddots & \ddots & \ddots & \\ & & & 1 & 3 & 1 \\ & & & & 1 & 3 \end{bmatrix}, \quad B = K = I, \quad X^{(0)} = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ -1 & 1 \\ 0 & 0 \\ \vdots & \vdots \\ 0 & 0 \\ 0 & 0 \end{bmatrix}.$$

Then $\Theta^{(0)} = \text{diag}\{2, 4\}$ and $W^{(0)} = AX^{(0)} - X^{(0)}\Theta^{(0)} = [-e_3, e_3]/\sqrt{2}$. The span of $[X^{(0)}, W^{(0)}]$ is equivalent to $\text{span}([e_1, e_2, e_3])$. However, `svqb()` always attempts to return an output S consisting of four linearly dependent vectors in both exact and floating-point arithmetic.

If we simply neglect the failure of `svqb()` and assume orthonormality of S (i.e., $S^T S = I$) in the subsequent call to `RayleighRitz()`, then we obtain $\theta_1 = 0$ as S is rank deficient. This is a spurious Ritz value since A is positive definite with smallest eigenvalue larger than 1. The connection between orthogonality error and results of Rayleigh–Ritz is analyzed in more detail in [4].

To overcome this difficulty, we modify `ortho()` to truncate basis vectors below roundoff error threshold. The eigenvalue decomposition in `svqb()` gives the form

$$U^T M U = \sum_{i=1}^{n_u} \theta_i z_i z_i^T,$$

where we have sorted eigenvalues $\theta_1 \geq \theta_2 \geq \dots \geq \theta_{n_u}$. Let $t \leq n_u$ be the number of leading eigenpairs that are above the drop threshold: $\theta_t \geq \theta_1 \cdot \tau_{\text{drop}}$, where the drop tolerance τ_{drop} is a small multiple of the machine precision μ_ϵ . The retained basis becomes

$$U^{(\text{out})} = U [z_1, z_2, \dots, z_t] \text{diag}\{\theta_1, \theta_2, \dots, \theta_t\}^{-1/2}.$$

It can be shown that under some mild assumption, basis truncation can significantly improve the robustness and efficiency of the LOBPCG algorithm. We refer to [4] for detailed analysis.

If maintaining a guaranteed minimum basis dimension is necessary, the basis can be padded with randomly generated B -orthogonalized columns. However randomized padding has never been necessary or useful in any of our experiments.

Our modifications are outlined in Algorithms 5 and 6. The implementation we tested still allows one call to `svqb()` without basis truncation in order to extract potentially useful information. However, subsequent iterations of the inner loop switch to the modified version to ensure a successful exit.

Algorithm 5 Modified orthogonalization procedure.

Input:

M is $m \times m$ symmetric positive definite metric.
 $U^{(\text{in})}$ is $m \times n_u^{(\text{in})}$ candidate basis.
 V is M -orthonormal external basis.
 $\tau_{\text{ortho}} > 0$ is relative orthogonality tolerance.

Output:

$U^{(\text{out})}$ is $m \times n_u^{(\text{out})}$, with $n_u^{(\text{out})} \leq n_u^{(\text{in})}$.
 $\text{span}([U^{(\text{out})}, V]) \supseteq \text{span}([U^{(\text{in})}, V])$.
1: **function** $U^{(\text{out})} = \text{orthoDrop}(M, U^{(\text{in})}, V, \tau_{\text{ortho}})$
2: Set τ_{replace} and τ_{drop} .
3: **do** $i = 1, 2, 3$
4: $U = U - V(V^T M U)$.
5: **do** $j = 1, 2, 3$
6: **if** $j = 1$ **then**
7: $U = \text{svqb}(M, U, \tau_{\text{replace}})$.
8: **else**
9: $U = \text{svqbDrop}(M, U, \tau_{\text{drop}})$.
10: **end if**
11: **while** $\frac{\|U^T M U - I_{n_u}\|}{\|M U\| \|U\|} > \tau_{\text{ortho}}$
12: **while** $\frac{\|V^T M U\|}{\|M V\| \|U\|} > \tau_{\text{ortho}}$
13: **end function**

Algorithm 6 SVQB with dropping

Input:

M is $m \times m$ symmetric positive definite metric.
 $U^{(\text{in})}$ is $m \times n_u^{(\text{in})}$.
 $\tau_{\text{drop}} > 0$ is tolerance.

Output:

$U^{(\text{out})}$ is $m \times n_u^{(\text{out})}$, with $n_u^{(\text{out})} \leq n_u^{(\text{in})}$.
 $\text{span}(U^{(\text{out})}) = \text{span}(U^{(\text{in})})$.
1: **function** $U^{(\text{out})} = \text{svqbDrop}(M, U^{(\text{in})}, \tau_{\text{drop}})$
2: $D = (\text{diag}(U^T M U))^{-1/2}$.
3: Solve $(D U^T M U D) Z = Z \Theta$ for Z, Θ .
4: Determine columns to keep $J = \{j : \theta_j > \tau_{\text{drop}} \max_i(|\theta_i|)\}$.
5: $U = U D Z(:, J) \Theta(J, J)^{-1/2}$.
6: **end function**

4.2 Improved basis selection strategy

The Rayleigh–Ritz procedure always computes orthonormal primitive eigenvectors Z satisfying

$$(R^{-T} S^T A S R^{-1}) Z = Z \Theta, \quad Z^T Z = I,$$

where R is the Cholesky factor of $S^T B S$, i.e., $S^T B S = R^T R$. The matrices Z and Θ can be partitioned conformally as

$$Z = \begin{bmatrix} Z_1 & Z_{1\perp} \\ Z_2 & Z_{2\perp} \end{bmatrix}, \quad \Theta = \begin{bmatrix} \Theta_x & 0 \\ 0 & \Theta_\perp \end{bmatrix}, \quad (5)$$

so that Z_1 and Θ_x are $k \times k$ matrices. For simplicity, the superscripts are omitted. We also omit diagonal scaling step in `RayleighRitz()`, as D can be absorbed into R . To construct the new search directions $[X, P] = S[C_x, C_p]$, HL's basis selection strategy uses

$$C_x = R^{-1} \begin{bmatrix} Z_1 \\ Z_2 \end{bmatrix}, \quad C_p = R^{-1} \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix}, \quad (6)$$

where $[Q_1^T, Q_2^T]^T$ is obtained by orthonormalizing

$$\begin{bmatrix} 0 \\ Z_2 \end{bmatrix} - \begin{bmatrix} Z_1 \\ Z_2 \end{bmatrix} \begin{bmatrix} Z_1 \\ Z_2 \end{bmatrix}^T \begin{bmatrix} 0 \\ Z_2 \end{bmatrix}$$

using SVQB.

We propose an improved strategy for constructing C_p based on the following observation. Because Z is an orthogonal matrix, we have

$$\begin{bmatrix} 0 \\ Z_2 \end{bmatrix} - \begin{bmatrix} Z_1 \\ Z_2 \end{bmatrix} \begin{bmatrix} Z_1 \\ Z_2 \end{bmatrix}^T \begin{bmatrix} 0 \\ Z_2 \end{bmatrix} = \begin{bmatrix} Z_{1\perp} \\ Z_{2\perp} \end{bmatrix} \begin{bmatrix} Z_{1\perp} \\ Z_{2\perp} \end{bmatrix}^T \begin{bmatrix} 0 \\ Z_2 \end{bmatrix} = \begin{bmatrix} Z_{1\perp} \\ Z_{2\perp} \end{bmatrix} Z_{2\perp}^T Z_2 = - \begin{bmatrix} Z_{1\perp} \\ Z_{2\perp} \end{bmatrix} Z_{1\perp}^T Z_1.$$

Therefore the blocks Q_1 and Q_2 required in (6) are completely determined by an orthonormal basis of the columns of $[Z_{1\perp}^T, Z_{2\perp}^T]^T Z_{1\perp}^T$. Since $[Z_{1\perp}^T, Z_{2\perp}^T]^T$ is already orthonormal, the task of finding Q_1 and Q_2 simplifies to that of finding an orthonormal basis of the columns of $Z_{1\perp}^T$. This can be achieved by performing an LQ or RQ factorization $Z_{1\perp} = L_{1\perp} Q_{1\perp}$. In practice, a Householder reflection based LQ factorization subroutine (e.g., `xGELQF` in LAPACK [2]) can be applied to guarantee the orthogonality even if $Z_{1\perp}^T$ does not have full column rank. Finally, we choose C_p as

$$C_p = R^{-1} \begin{bmatrix} Z_{1\perp} \\ Z_{2\perp} \end{bmatrix} Q_{1\perp}^T.$$

This improved strategy replaces the call to `ortho()` required by the HL strategy with an LQ factorization, which is both cheaper and numerically more stable. This improvement is outlined in Algorithms 7. Our strategy ensures that in each step $[X, P]$ always has full column rank (as long as the number of columns here does not exceed that of A , which is a plausible assumption in practice). Thus basis truncation is only required when orthonormalizing W .

4.3 Detecting convergence

In some of our numerical experiments with the HL implementation of LOBPCG, we observed both unexpectedly high and low number of iterations required to reach convergence. One such example, **Andrews**, is a standard eigenvalue problem from the University of Florida Sparse Matrix Collection (UFSMC).¹ **Andrews** is a $60,000 \times 60,000$ symmetric matrix with 760,154 nonzero elements. We

Algorithm 7 Rayleigh–Ritz with improved basis selection

Input:

S is an $m \times n_s$ matrix forming a basis for the search subspace.
 n_x is the number of extreme eigenpair approximations to return.
 n_c is the number of converged eigenpairs from the previous iteration.
`useOrtho = true` indicates $S^T B S = I$.

Output:

C is $n_s \times (2n_x - n_c)$. First n_x columns are C_x followed by $n_x - n_c$ giving C_p .
 If `useOrtho` is newly set, repeat iteration with `ortho`.
 Output satisfies $C^T (S^T B S) C = I$ and $C^T (S^T A S) C = \Theta$.

1: **function** $[C, \Theta, \text{useOrtho}] = \text{RayleighRitzModified}(S, n_x, n_c, \text{useOrtho})$

2: **if** `useOrtho` **then**

3: Solve $(S^T A S) Z = Z \Theta$, where Z is partitioned as in (5).

4: LQ factorize $L_{1\perp} Q_{1\perp} = Z_{1\perp}$.

5:

$$C_x = \begin{bmatrix} Z_1 \\ Z_2 \end{bmatrix}, \quad C_p = \begin{bmatrix} Z_{1\perp} \\ Z_{2\perp} \end{bmatrix} Q_{1\perp}^T.$$

6: **else**

7: $D = (\text{diag}(S^T B S))^{-1/2}$

8: Cholesky factorize $R^T R = D S^T B S D$.

9: Solve $(R^{-T} D S^T A S D R^{-1}) Z = Z \Theta$.

10: LQ factorize $L_{1\perp} Q_{1\perp} = Z_{1\perp}$.

11:

$$C_x = D R^{-1} \begin{bmatrix} Z_1 \\ Z_2 \end{bmatrix}, \quad C_p = D R^{-1} \begin{bmatrix} Z_{1\perp} \\ Z_{2\perp} \end{bmatrix} Q_{1\perp}^T.$$

13: Update Θ to represent partial inner products

$$\Theta = \begin{bmatrix} \Theta_x & 0 \\ 0 & Q_p(:, 1 : n_x - n_c)^T \Theta_\perp Q_p(:, 1 : n_x - n_c) \end{bmatrix}.$$

14: **end function**

attempted to find the lowest 400 eigenpairs using a block size of 440 columns. We set the convergence criterion to

$$\frac{\|r_i\|_2}{\|\theta_i\| \|x_i\|_2} = \frac{\|Ax_i - \theta_i x_i\|_2}{\|\theta_i\| \|x_i\|_2} \leq \tau, \quad (7)$$

which is the default one provided in the Anasazi package [3]. The tolerance is set to $\tau = 10^{-4}$. This test run was forced to exit without having converged after 1,000 iterations.

Another test problem showed the opposite difficulty with convergence. The matrix pencil `filter2D`, which is also available from UFSMC, has symmetric sparse matrices A and B of dimension 1,668; A has 10,750 nonzero elements and B is diagonal. In this test case we also sought the lowest 400 eigenvalues using 440 columns per block and the same convergence tolerance, and

use the convergence criterion

$$\frac{\|r_i\|_2}{|\theta_i|\|x_i\|_B} = \frac{\|Ax_i - \theta_i Bx_i\|_2}{|\theta_i|\|x_i\|_B} \leq \tau. \quad (8)$$

The algorithm reported convergence immediately after the first iteration. We emphasize that the first iteration is merely `RayleighRitz()` on a random matrix.

These difficulties result from the relative residual computation that is typically used to detect convergence. The criteria (7) and (8) have two problems. The first problem is that (8) lack scaling invariance, i.e., scaling B actually changes the criterion. As a result, convergence detection using such a measure is somewhat arbitrary. In the `filter2D` example, $\|B\| \approx 10^{-10}$ which makes convergence too easy to achieve. Of course, this could be repaired by forcing a uniform scaling of A and B or including $\|A\|$ and $\|B\|$ in the denominator. The second problem with relative residual convergence measures persists even if B is the identity. In fact, for an eigenvalue with small magnitude, it may not be possible to compute a residual in floating point arithmetic that satisfies a criterion of the form (7) or (8). In the `Andrews` example, the smallest eigenvalue is less than 10^{-14} in magnitude and $\|A\| \approx 10$. Ill-conditioning of A does not permit the smallest eigenvalue to be known to four digits of precision.

We employ an alternative backward stable convergence criterion:

$$\frac{\|r_i\|_2}{(\|A\|_2 + |\theta_i|\|B\|_2)\|x_i\|_2} \leq \tau. \quad (9)$$

For large matrices the 2-norms on A and B can be estimated with very little computational cost by using a $k \times m$ Gaussian random matrix Ω with $k \ll m$. The inequality $\|\Omega A\|_F \leq \|\Omega\|_F \|A\|_2$ implies that

$$\|A\|_2^{(\Omega)} \stackrel{\text{def}}{=} \frac{\|\Omega A\|_F}{\|\Omega\|_F} \leq \|A\|_2.$$

This guarantees our convergence criterion is satisfied if

$$\frac{\|r_i\|_2}{(\|A\|_2 + |\theta_i|\|B\|_2)\|x_i\|_2} \leq \frac{\|r_i\|_2}{\left(\|A\|_2^{(\Omega)} + |\theta_i|\|B\|_2^{(\Omega)}\right)\|x_i\|_2} \leq \tau.$$

Using this convergence test, `Andrews` converges after performing 56 iterations. Likewise, `filter2D` converges after performing 10 iterations. Finally, we remark that the discussion on convergence criterion is valid not only for LOBPCG, but also for more general Hermitian and non-Hermitian eigensolvers.

5 Efficiency improvements

The following efficiency improvements can be safely included in LOBPCG without sacrificing algorithmic stability. Our algorithm will be summarized at the end of this section.

5.1 Efficient matrix multiply and update

In the basis selection stage, the update $X^{(i+1)}$ and the search direction $P^{(i+1)}$ are supposed to overwrite the corresponding parts in $S^{(i)}$. However, their calculation also relies on $S^{(i)}$. Therefore,

a practical implementation may look like

$$T \leftarrow S^{(i)} \begin{bmatrix} C_x^{(i+1)}, C_p^{(i+1)} \end{bmatrix}, \quad S^{(i+1)}(:, 1 : n_x + n_p) \leftarrow T. \quad (10)$$

At first glance, this step requires a lot of memory for the workspace T .

In our implementation, we partition the matrices $S^{(i)}$, $X^{(i+1)}$, and $P^{(i+1)}$ into chunks of row blocks and update them chunk by chunk, i.e.,

$$S^{(i)} = \begin{bmatrix} S_1^{(i)} \\ S_2^{(i)} \\ \vdots \end{bmatrix}, \quad T \leftarrow S_j^{(i)} \begin{bmatrix} C_x^{(i+1)}, C_p^{(i+1)} \end{bmatrix}, \quad S_j^{(i+1)}(:, 1 : n_x + n_p) \leftarrow T. \quad (11)$$

By this partitioning the memory requirement for the workspace T is largely reduced. Actually very often there is no need to allocate additional memory for T , as the space for storing $AW^{(i)}$, which is not needed anymore in the current iteration, can be reused as workspace here.

In addition, we prefer using such a block row partitioning strategy even if there is enough memory to hold a big workspace. It has been observed that the use of (11) often leads to better performance compared to using (10) by directly calling BLAS. We refer to [1] for more discussions.

Finally, we remark on the storage of $S^{(i)}$. In general, contiguous memory access is preferred from the performance perspective. One naturally idea is to arrange $S^{(i)}$ in the order of $[X^{(i)}, W^{(i)}, P^{(i)}]$, so that the memory access pattern of $W^{(i)}$ remains unchanged even in the first iteration of LOBPCG. We suggest to use the order $[X^{(i)}, P^{(i)}, W^{(i)}]$ instead so that (11) can be performed with contiguous memory access. In addition, the columns of $W^{(i)}$ are stored in reversed order compared $X^{(i)}$. With this ordering, deflation always drops the right most columns in $S^{(i)}$ and does not require additional data movement.

5.2 Implicit product updates

When there is sufficient memory to store S , AS , and BS if $B \neq I$, HL suggest a possible improvement to efficiency by employing implicit product updates. Given block updates $X^{(i+1)} = S^{(i)}C_x^{(i+1)}$ and $P^{(i+1)} = S^{(i)}C_p^{(i+1)}$, matrix products can be implicitly updated using the same transformations:

$$\begin{aligned} AX^{(i+1)} &= AS^{(i)}C_x^{(i+1)}, & AP^{(i+1)} &= AS^{(i)}C_p^{(i+1)}, \\ BX^{(i+1)} &= BS^{(i)}C_x^{(i+1)}, & BP^{(i+1)} &= BS^{(i)}C_p^{(i+1)}, \end{aligned}$$

This is beneficial when direct matrix multiplication (i.e., the application of A or B) is expensive, which is often the case in practice. Using a similar technique discussed in Section 5.1, we perform these updates by chunks of row blocks.

We extend this technique to reduce computation of block inner products in the projection matrices

$$S^{(i)T}AS^{(i)} = \begin{bmatrix} X^{(i)T}AX^{(i)} & X^{(i)T}AW^{(i)} & X^{(i)T}AP^{(i)} \\ \dots & W^{(i)T}AW^{(i)} & W^{(i)T}AP^{(i)} \\ \dots & \dots & P^{(i)T}AP^{(i)} \end{bmatrix}$$

and

$$S^{(i)T}BS^{(i)} = \begin{bmatrix} X^{(i)T}BX^{(i)} & X^{(i)T}BW^{(i)} & X^{(i)T}BP^{(i)} \\ \dots & W^{(i)T}BW^{(i)} & W^{(i)T}BP^{(i)} \\ \dots & \dots & P^{(i)T}BP^{(i)} \end{bmatrix}.$$

Most implementations we have seen take advantage of some known structure within each block:

$$X^{(i)T}AX^{(i)} = \Theta^{(i)}, \quad X^{(i)T}BX^{(i)} = I.$$

In fact, we also have

$$X^{(i)T}AP^{(i)} = 0, \quad X^{(i)T}BP^{(i)} = 0, \quad P^{(i)}BP^{(i)} = I,$$

because $P^{(i)}$ is in the orthogonal complement of the previous solution. Implicit updating can also be used to avoid an additional block inner product

$$P^{(i)T}AP^{(i)} = C_p^T \left(S^{(i-1)T}AS^{(i-1)} \right) C_p.$$

Every block involving $W^{(i)}$ must be directly computed unless $B = I$ and the preconditioner is $K = I$. In that case, $W^{(i)}$ is the block of residuals which must be orthogonal to the search subspace from which previous Rayleigh–Ritz solutions were formed including both $X^{(i)}$ and $P^{(i)}$ yielding $X^{(i)T}W^{(i)} = 0$ and $W^{(i)T}P^{(i)} = 0$. Since every block inner product must move $\mathcal{O}(2mn_x)$ data through processors, every direct computation avoided significantly improves performance.

However, implicit updates accumulate roundoff error which can sometimes hinder stability and convergence. In order to ensure the reliability of implicit updates, we perform some simple roundoff error analysis below.

Let us consider an implicit update of the form

$$\hat{X} = XT, \quad A\hat{X} = AXT,$$

in which AX is kept in memory and multiplied with T from the right. Suppose we have arrays representing a basis X and product $\mathbf{fl}(AX) = AX + \epsilon_1 \|AX\| E_1$, where the scalar $\epsilon_1 \geq 0$ is chosen in the way that the matrix E_1 is normalized as $\|E_1\| = 1$. When applying the transformation T , floating point arithmetic gives

$$\hat{X} = \mathbf{fl}(XT) = XT + \epsilon_2 \|X\| \|T\| E_2.$$

However we can define the new basis to be exactly represented by the resulting array \hat{X} . Computing the product directly in floating point arithmetic leaves representation error

$$\mathbf{fl}(A\hat{X}) = A\hat{X} + \epsilon_3 \|A\| \|\hat{X}\| E_3.$$

Alternatively, we could apply the transformation to the stored product $\mathbf{fl}(AX)$ to obtain

$$\mathbf{fl}(\mathbf{fl}(AX)T) = AXT + \epsilon_1 \|AX\| E_1 T + \epsilon_4 \|AX\| \|T\| E_4.$$

We can express this error in the new basis by substituting $AXT = A\hat{X} - \epsilon_2 \|X\| \|T\| AE_2$ to write the error as

$$\mathbf{fl}(\mathbf{fl}(AX)T) = A\hat{X} + \epsilon_5 \|A\| \|\hat{X}\| E_5,$$

where we have defined the composite error

$$\epsilon_5 \|A\| \|\hat{X}\| E_5 = \epsilon_1 \|AX\| E_1 T - \epsilon_2 \|X\| \|T\| AE_2 + \epsilon_4 \|AX\| \|T\| E_4.$$

Similar to the choice of ϵ_1 and E_1 , here we impose the normalization condition $\|E_2\| = \|E_3\| = \|E_4\| = \|E_5\| = 1$. Using the triangle inequality with $\|E_1 T\| \leq \|T\|$, $\|AE_2\| \leq \|A\|$, and $\|AX\| \leq \|A\|\|X\|$, we arrive at

$$\epsilon_5 \leq (\epsilon_1 + \epsilon_2 + \epsilon_4) \frac{\|X\|\|T\|}{\|\hat{X}\|}.$$

From the roundoff error analysis, we conclude that implicit updates are in general safe if $T = C_x$ or $T = C_p$ is used, as $\|T\| = 1$.

However, we remark that implicit updates should not be used in `ortho()` and `svqb()` when a nontrivial metric B is involved. When performing

$$U^{(1)} = U^{(0)} - V \left((BV)^T U^{(0)} \right), \quad U^{(2)} = U^{(1)} \left(DZ\Theta^{-1/2} \right),$$

implicit updates of the form

$$BU^{(1)} = BU^{(0)} - BV \left((BV)^T U^{(0)} \right), \quad BU^{(2)} = BU^{(1)} \left(DZ\Theta^{-1/2} \right)$$

are valid in exact arithmetic. But this is in general a bad idea, especially for $BU^{(2)}$, because the matrix $DZ\Theta^{-1/2}$ can be very ill-conditioned. We have observed that the use of such updates often leads to failure of termination in the inner loop of `ortho()`, if the candidate basis $U^{(0)}$ has a condition number in the metric B of 10^6 or higher. Nearly all randomized tests will fail under this circumstance. Indeed, the original purpose for using `ortho()` was to handle such ill-conditioned bases that cause LOBPCG to fail otherwise. Therefore, we do not recommend to use implicit update in `ortho()` and `svqb()`.

5.3 Skipping orthogonalization

Although constructing an orthonormal basis for S guarantees that `RayleighRitz()` will not fail, the construction process itself can be costly and sometimes unnecessary. The principal extra cost is contained in the call to `ortho()` used to complete block W . Even if we assume each step within Algorithm 3 succeeds on the first iteration, the corresponding basis update computations would be

$$W \leftarrow W - [X, P]([X, P]^T B W), \quad W \leftarrow W(DZ\Theta^{1/2}).$$

As a result, the memory block containing W must be accessed at least twice.

If `ortho()` is skipped, which forces `RayleighRitz()` to construct and apply Cholesky factors of $S^T B S$, the transformations that would have been performed in `ortho()` are subsumed by updates to X and P . As a result, iterations that skip `ortho()` reduce memory movement by more than two full passes over W . Furthermore, `svqb()` requires solving an $n_x \times n_x$ eigenvalue problem which is much more time consuming than the corresponding Cholesky decomposition when n_x is not tiny.

In order to take advantage of this possible performance improvement without sacrificing stability, we need to determine when the Cholesky decomposition $R^T R = S^T B S$ becomes unreliable. As R^{-1} or R^{-T} is applied three times, a simple heuristic is to require $\text{cond}(R)^{-3} \geq \tau_{\text{skip}}$, where τ_{skip} is a modest multiple of the machine precision.

Knowing this allows us to skip orthogonalization of W initially. When the condition number exceeds the safe threshold we switch to iterations that apply full orthogonalization. Note that our method to construct orthogonal $P^{(i)}$ blocks is not expensive and therefore not worth skipping.

Algorithm 8 Robust and efficient LOBPCG algorithm

Input:

- $X^{(0)}$ is $m \times n_x$ initial approximate eigenvectors.
- $n_v \leq n_x$ is the number of converged eigenvectors requested.
- τ is the threshold used to determine eigenpair convergence.

Output:

- X is $m \times n_v$ matrix of approximate eigenvectors.
- Λ is $n_v \times n_v$ diagonal matrix of approximate eigenvalues.

```
1: function  $[X, \Lambda] = \text{lobpcg}(X^{(0)}, n_v, \tau)$ 
2:   Set  $\tau_{\text{ortho}}$ .
3:    $[C^{(1)}, \Theta^{(1)}] = \text{RayleighRitz}(X^{(0)})$ 
4:    $X^{(1)} = X^{(0)}C^{(1)}$ .
5:    $R^{(1)} = AX^{(1)} - BX^{(1)}\Theta^{(1)}$ .
6:    $n_c = 0$ ; useOrtho = false;  $P^{(1)} = []$ .
7:   do  $i = 1, 2, \dots$ 
8:     if useOrtho  $W^{(i)} = \text{orthoDrop}(B, R^{(i)}, [X^{(i)} P^{(i)}], \tau_{\text{ortho}})$ .
9:     else  $W^{(i)} = R^{(i)}$ .
10:     $S^{(i)} = [X^{(i)}, P^{(i)}, W^{(i)}]$ .
11:     $[C^{(i+1)}, \Theta^{(i+1)}, \text{useOrtho}] = \text{RayleighRitzModified}(S^{(i)}, n_x, n_c, \text{useOrtho})$ .
12:     $[X^{(i+1)}, P^{(i+1)}] = S^{(i)}[C_x, C_p]$ .
13:     $R^{(i+1)} = AX^{(i+1)} - BX^{(i+1)}\Theta^{(i+1)}$ .
14:    Determine number of converged eigenpairs  $n_c$ .
15:  while  $n_c < n_v$ 
16:  Return converged eigenpairs in  $X$  and  $\Lambda$ .
17: end function
```

After $\text{cond}(R)$ passes the safe threshold, subsequent iterations tend to remain above the threshold. As a result, we never attempt to switch back to iterations that skip $\text{ortho}()$.

Another shortcut to take is to exit $\text{ortho}()$ early when it is safe to do so. Just as conditioning of S^TBS allows us to identify when $\text{ortho}()$ may be safely skipped, we can also use the condition number of W^TBW within $\text{svqb}()$ to predict acceptable orthogonality error. The update $W^{(2)} = W^{(1)}(DZ\Theta^{-1/2})$ produces relative orthogonality error of magnitude $\mu_e \text{cond}(\Theta^{-1/2})$, therefore we can avoid computing the resulting orthogonality error in $W^{(2)T}BW^{(2)}$ when $\text{cond}(\Theta^{-1/2})$ is small. Likewise, relative orthogonality error testing in the outer loop of $\text{ortho}()$ may be skipped if the $\text{svqb}()$ transformation was well-conditioned on the *first* iteration of the inner loop. This improvement usually allows us to avoid three block inner products for each call to $\text{ortho}()$.

6 Numerical examples

In this section we demonstrate the efficiency and robustness of our implementation of Algorithm 8 by several examples performed on the Linux Cluster, Edison, at the National Energy Research Scientific Computing Center (NERSC).² Each compute nodes of Edison has two 12-core Intel “Ivy Bridge” processors at 2.4 GHz, and 64 GB DDR3 1866 MHz memory. Our tests are performed on

²<http://www.nersc.gov/users/computational-systems/edison/>

a single compute node of Edison, using 24 cores unless otherwise explicitly stated.

Algorithm 8 is implemented for shared memory architectures using Fortran and OpenMP, and is compared with Blopex [8] and Anasazi [3]. We also implement Hetmaniuk–Lehoucq’s LOBPCG algorithm for comparison. To make the performance comparison more meaningful, we add OpenMP directives to Blopex to parallelize most of loop-level operations including dense linear algebra. As in most cases the time to solution instead of the number of iterations is of practical interest, we report the wall clock time in performance tests.

The test matrices we use are shown in Table 1. Most of these test matrices are available from the University of Florida Sparse Matrix Collection, with the exception of **C60**, which is generated from a MATLAB version of the PARSEC [9] software called RSDFE for a Buckyball molecule. In all tests we seek 1% (up to 500) of the eigenpairs with minimal eigenvalues. Basis blocks are padded by 10%. The same convergence criterion (9) is used for all implementations, except for tests performed in Section 6.1. The convergence tolerance is set to 10^{-4} . We have altered the source code of both Blopex and Anasazi implementations of LOBPCG to use our convergence criterion. Programs are allowed to perform up to 2,000 iterations, and up to four wall clock hours.

Table 1: A list of test matrices.

case	matrix	size	nnz	eigenpairs	block dim.
1	C60	17,576	212,390	176	194
2	Si5H12	19,896	738,598	199	219
3	c-65	48,066	360,428	481	529
4	Andrews	60,000	760,154	500	550
5	Ga3As3H12	61,349	5,970,947	500	550
6	Ga10As10H30	113,081	6,115,633	500	550

6.1 Convergence comparisons

The number of iterations performed by an implementation of LOBPCG will depend on the method used to detect convergence and the corresponding threshold. This introduces a difficulty when we attempt to compare different implementations. Because we use the modified convergence criterion (9), it is possible that our algorithm benefits from performing fewer iterations compared to other implementations, which obfuscates the meaning of direct timing comparisons.

In order to show that our convergence criterion is a fair improvement, we first compare each implementation using its original convergence method (marked with suffix -OC) and our modification. We also test our own conservative implementation of the Hetmaniuk–Lehoucq algorithm (CHL). This version does not perform any implicit updates or employ other performance improvements marked as optional in [6].

The test results are collected in Table 2. For **C60**, Blopex-OC fails due to a negative pivot within Cholesky factorization. In the case of **Andrews**, both Anasazi-OC and CHL-OC do not converge after running for four hours, and hence are considered as failures. Since Anasazi-OC and CHL-OC force convergence in order, iteration cannot terminate as the minimum eigenvalue is too close to zero to satisfy the relative residual threshold in floating point arithmetic. In fact Blopex-OC also does not fully succeed with this example though it returns converged eigenpairs within the allowed number of iterations, because the minimum eigenpair is missing. Clearly each implementation benefits from the new convergence criterion.

Table 2: Execution time for different convergence criteria

matrix	Anasazi-OC	Anasazi	Blopex-OC	Blopex	CHL-OC	CHL
C60	947.40	21.02	failed	14.15	26.63	17.15
Si5H12	53.48	42.49	49.84	29.57	42.66	31.67
Andrews	failed	614.10	383.70	318.90	failed	276.01

Figure 1: Execution time relative to the CHL implementation for tests performed with 1 core (left) and 24 cores (right). Relative wall time over 2.5 correspond to failures due to nonpositive pivots in the Cholesky factorization.

6.2 Fixed core performances

In the remaining of this section we will stick to the convergence criterion (9) for all implementations. This ensures that when we compare performance, we are doing so for the same effective workload. In addition to the conservative implementation of Hetmaniuk–Lehoucq algorithm (CHL), we also test an aggressive implementation (AHL) using the implicit updates they suggest.

The tests are performed for both one core and 24 cores on Edison. Wall clock times are plotted in Figure 1 relative to CHL because it is a reliable reference. It can be seen that both CHL and AHL are more robust than Blopex due to basis orthogonalization, but also sacrifice the performance a bit. Our implementation of Algorithm 8 is the fastest in most cases, while remaining robust. It also scales well for 24 cores.

6.3 Scalability tests

Our implementation of Algorithm 8 demonstrates promising scalability on 24 cores in Figure 1. To have a closer look on the thread scalability, we perform tests on Si5H12, for which all implementations succeed, using different numbers of cores. The execution time is plotted in Figure 2.

The parallel scaling tests for Anasazi, AHL, and—to a lesser extent—CHL demonstrate an interesting artifact: Performance drops for twelve core tests. Note that each 24-core node on Edison is separated into two 12-core non-uniform memory access (NUMA) nodes. However the performance drop is not fully due to the NUMA penalty, as it does not occur when more than twelve cores are used. The implementation difference between CHL and AHL illuminates the source of this phenomenon. AHL performs additional tall skinny GEMM during implicit basis updates. This reveals an inefficiency in matrix multiply when the NUMA node saturates. The strategy of updating basis

Figure 2: Execution time for the test case Si5H12 with respect to the number of cores.

in a block row manner discussed in Section 5.1 requires a single synchronization—communicating the small update matrix—before becoming naively parallel. As a result, the phenomenon vanishes entirely in our implementation of Algorithm 8.

Finally we examine the effect of scaling the number of desired eigenpairs and the corresponding block dimension, because handling a large number of eigenpairs is one of the motivations of this work. We choose **Andrews** as the test case, as all of the implementations we test are successful on this matrix. The execution time on 24 cores is shown in Figure 3. Our implementation of Algorithm 8 consistently outperforms other implementations.

7 Concluding remarks

We developed a number of techniques to improve the stability of the LOBPCG algorithm, especially when the algorithm is used to compute a relatively large number of eigenpairs. We showed that a careful implementation of these techniques can also lead to improvement in the efficiency of the algorithm. We demonstrated the improvement by several numerical examples performed on single processor and multi-core systems using OpenMP parallelization. A distributed memory parallel version of the code is currently being developed. We expect a similar type of performance gain to be achieved in the distributed memory parallel version for much larger problems arising from various scientific applications.

Acknowledgments

We would like to thank Lin Lin, Osni Marques, and Eugene Vecharynski for several useful discussions regarding this work.
